

Delirium

Delirium is described as an alteration in cognition and awareness. Typically, delirium presents quickly and over a short period of time and is always secondary to some condition that resolves over time. The patient with delirium is easily distracted and requires frequent assistance in focusing attention. Delirium may cause the patient's speech to be incoherent due to rambling, and may appear irrelevant and pressured. Typically, delirium causes the patient to be disoriented to place and time and can cause hallucinations and short-term memory loss. Some predisposing factors of delirium include: illness, hypoxia, head trauma, seizures, substance abuse, substance withdrawal, systemic infections, and electrolyte imbalances.

PLAY PICMONIC

Mechanism

Rapid Onset

Rapid-rabbit On-switch

A key distinguishing feature of delirium is that the onset is not gradual and may be sudden, within minutes to hours to days.

Reversible

Reversed-hat

Contrasted with dementia, delirium is reversible by treating the underlying cause of the condition, such as infection, hypoxia, drug intoxication, etc.

Fluctuating Course

Fluctuating Course

Delirium is characterized by a fluctuating course, meaning symptoms can vary in severity throughout the day, often worsening in the evening or at night. This waxing and waning pattern is a key distinguishing feature from other cognitive disorders like dementia, which tend to have a stable or progressively worsening course.

Secondary to Another Illness

(2) Tutu Illness

Delirium is always secondary to an underlying medical condition. Examples include infection, metabolic imbalance, medication effects, substance intoxication/withdrawal, or organ failure.
br>lt is not a primary psychiatric disorder but a manifestation of an acute disturbance in brain function triggered by a systemic cause. Management of delirium includes finding the underlying cause and treating it.

Assessment

Short Attention Span

Shorts with Attention Span

A patient with delirium often has a short attention span. They may experience difficulty focusing and will require frequent reminding and refocusing on tasks they attempt to complete.

Decline in Cognition

Down-arrow Cog-brain

Delirium often leads to a decline in cognition. This decline may cause the patient to be disoriented in person, place, or time, experience poor judgment, and have impairments in memory.

Altered Sleep Wake Cycle

Altered Sleep Cycle

An altered sleep-wake cycle is a common feature of delirium. This often presents as daytime drowsiness and nighttime agitation/insomnia. Patients may be awake at night and excessively sleepy during the day. This is because of a disruption in the normal circadian rhythm. Altered sleep-wake cycle is an early and sensitive indicator of delirium, and this helps distinguish delirium from other cognitive disorders like dementia.

Hallucinations

Halloween-hallucination

Being "delirious" is often a combination of any or all three - hallucinations, delusions, and illusions. They may see, hear, or perceive things differently, fabricate them entirely, or misinterpret reality.

Illusions (Misperceptions)

Illusionary-stairs

Illusions in delirium are misinterpretations of actual sensory input. For example, mistaking a coat on a chair for a person. It differs from hallucinations, which occur without external stimuli.

Diffuse EEG Slowing

Fuse EEG-cap Slow-snail

Electroencephalogram in delirium often shows diffuse background rhythm slowing, reflecting widespread brain dysfunction.
br>Useful in differentiating delirium (slowing) vs psychosis (normal EEG) vs seizure (epileptiform activity).

TREATMENT

Treat Underlying Disorder

Treat Underlying Diseased-guy

Treating the underlying cause is the primary management of delirium, but other than that, supportive measures are crucial. This may include nonpharmacologic interventions such as maintaining orientation with clocks and calendars, ensuring proper lighting, promoting normal sleep-wake cycles, and minimizing sensory overload or deprivation. Providing frequent reorientation, encouraging the presence of family members, and ensuring adequate hydration and nutrition can also help reduce the severity and duration of symptoms.

Providing frequent reorientation, encouraging the presence of family members, and ensuring adequate hydration and nutrition can also help reduce the severity and duration of symptoms.

Antipsychotics

Ant-tie-psychiatrist

Antipsychotics such as haloperidol may be used short-term for severe agitation in delirium, especially when the patient poses a danger to themselves or others. Benzodiazepines should be avoided unless delirium is due to alcohol or benzodiazepine withdrawal.
