Opioid Use Disorder and Withdrawal Assessment (Formerly Opioid Abuse and Withdrawal Assessment)

Prolonged use of opioids leads to drug tolerance and dependency. The development of opioid use disorder can stem from an individual increasing the amount and frequency of opioids taken to relieve pain from a medical issue. This use disorder can also come from individuals obtaining opioids from illegal sources for recreational use. The Opioid Withdrawal Assessment is a tool used to evaluate symptoms frequently seen in opioid withdrawal patients. The Assessment is used to determine the patient's level of physical dependence on opioids. In order to minimize opioid abstinence syndrome, gradually taper the patient off opioids.

PLAY PICMONIC

Abuse Assessment

Euphoria

U-flowers

Euphoria is an exaggerated feeling of elation. Opioids activate the mu and kappa receptors and initially induce feelings of euphoria. Although opioids create euphoria and decrease pain perception, their pleasurable effect contributes to drug misuse.

Miosis

Mice-eyes

Opioids stimulate the oculomotor nerve and cause miosis by constricting the pupils to "pinpoint" sizes. Keep bright lights during the daytime to compensate for impaired vision related to miosis.

CNS Depression

Down-arrow CNS-brain

Opioids depress the central nervous system (CNS). Symptoms include drowsiness, mental clouding, impaired attention and memory, slurred speech, and psychomotor retardation. Patients should be advised to avoid hazardous activities, such as driving. . In severe cases, opioid overdose symptoms may present as slow and shallow breathing, blue lips and fingernails, clammy skin, convulsions and coma, that may be fatal and will require emergency treatment.

Abuse Withdrawal

Yawning

Yawning

Yawning is an initial reaction to abstinence syndrome in patients highly dependent on opioids. Although the exact mechanism of yawning remains undetermined, a greater presence of opioid neurotransmitters decreases the frequency of yawning. Therefore, the sudden absence of opioids results in increased yawning.

Gooseflesh

Goosebumps

The side effect of goosebumps leads to the term “Cold Turkey” with sudden cessation of opioids. Gooseflesh, or piloerection, is an involuntary reflex caused by sympathetic stimulation. During opioid withdrawal, the body attempts to compensate by overly stimulating the sympathetic system.

Sweating

Sweaty sweatband

With sudden opioid cessation, the body develops sympathetic hyperactivity, exemplified by diaphoresis or sweating.

Rhinorrhea

Runny-nose

Rhinorrhea can occur with abstinence syndrome in patients highly dependent on opioids. The patient will experience sympathetic hyperactivity as the body tries to compensate for lack of opioid stimulation. Rhinorrhea is a symptom caused by excessive sympathetic activity.

Kicking Movements

Kicking

Opioid use disorder leads to constant physiological stimulation. During opioid withdrawal, the body reacts by manifesting with physical symptoms, such as uncontrollable kicking movements.

Consideration

Naloxone

Nail-lock

Opioid intoxication may be treated with the narcotic antagonist naloxone (Narcan). This medication is a competitive antagonist at opioid receptors and can reverse the opioid effects, such as sedation, euphoria, and analgesia. Naloxone will also create an immediate withdrawal reaction. **Caution** naloxone is only effective for (20 90 minutes). Individuals should be monitored closely as effects of opioids may outlast naloxone.
